Durbin's Algorithm

Algorithm 1 Algorithm 5 from Durbin's paper

```
function FIND SET MAXIMAL MATCHES FROM Z(z)
    for k \leftarrow 0 to N do
        e, f, g \leftarrow Update \ Z \ Matches(k, z, e, f, g)
function UPDATE Z_MATCHES(k, z, e, f, g)
    f' \leftarrow w(k, f, z[k])
                                                                       \triangleright a_k, d_k and y_i^k as in Durbin's paper
    g' \leftarrow w(k, g, z[k])
    if f' < g' then
                                                         \triangleright if k is N - 1 report matches from e_k to N - 1
        e' \leftarrow e_{\nu}
    else
                                                                                ▷ report matches from e to k
        e' \leftarrow d_{k+1}[f'] - 1
        if z[e'] = 0 and f' > 0 then
             f' \leftarrow \sigma' - 1
             while z[e'-1] = v_{e'}^{k+1}[e'-1] do e' \leftarrow e'-1
             while d_{k+1}[f'] \leq e'' \operatorname{do} f' \leftarrow f' - 1
        else
             \varrho' \leftarrow f' + 1
             while z[e'-1] = y_{s'}^{k+1}[e'-1] do e' \leftarrow e'-1
             while g' < M and d_{k+1}[g'] < e' do g' \leftarrow g' + 1
    return e', f', g'
```

Outline

- The Old Idea
- The New Idea
- BitVector Version
- Matching Statistics

New Idea I

Let's take a step back and get closer to Durbin's original idea.

At the moment we save:

- the position of every head of a run
- a boolean to mark if the first run is composed by zeros or ones
- the c value of the column
- \blacksquare a single value for u and v (that are as in Durbin)
- the whole divergence array, actually the LCP array, (WIP)

New Idea I

```
column: 5
start with 0? yes, c: 15
0
    0
   5
0 5 4 1 3 5 5 5 5 5 5 0 5 5 5 2 5 1 5 5
```

Figura: Example, column 5: 0010111100000000000

New Idea II

uv values trick

Values u and v increase alternately in the biallelic case so we save every time the only value that increase at the head of a run.

The, with a simple If/Else selection based on the first element of the column and the index of the run and on being even or odd of the index we can extract both u and v values. Infact the two values are, alternatively, saved in the current index and in the previous one.

$w(i, \sigma)$ function

We can use the same *LF-mapping* as in Durbin but we have to consider sometimes an *offset* between the position of the head of the run, that's *i*, which contains the "virtual" index, and the index itself.

$$w(i,\sigma) = \begin{cases} u[i] + offset & \text{if } \sigma = 0\\ c + v[i] + offset & \text{if } \sigma = 1 \end{cases}$$

New Idea III

External haplotype matches

Than we proceed as in Durbin, updating f and g using $w(i, \sigma)$.

Every time we "virtually" use indexes over the whole column but actually run heads plus offsets are used.

In case we update e using f and the divergence/LCP array (**WIP**). In order to update e we should in theory follow the line indicated in i+1 by f in the original panel which we have not memorized. So, at most at a cost of O(r) for every column, we proceed to reverse te use of u and v to move backwards between the columns virtually following a row of the original panel.

Than we use the divergence/LCP array (**WIP**) to update f and g depending on the case.

After detect a match, we can know the cardinality of the lines that match but not what they are,

New Idea IV

WIP

At the moment *divergence array* is saved as an sdsl::int_vector<> on which it's used sdsl::util::bit_compress() in order to save space. The original idea of thresholds seems to me absolutely not applicable but maybe we can think of storing only a subset of the *divergence/LCP array* and I'm thinking how to do it.

Testing

Benchmark

At the moment I'm testing the implementation using the sample data (VCF files) at:

https://github.com/ZhiGroup/Syllable-PBWT/tree/master/sample_data (the panel is 900×500 with 100 queries).

Outline

- The Old Idea
- 2 The New Idea
- BitVector Version
- Matching Statistics

The column data I

We save, for every column:

- a bit vector of the same length of the dense PBWT column, with 1 in every position before a head of a run
- 2 bit vector that can be queried to obtain *u* and *v* value. So we have a bitvector for zeros that contains 1 in position *i* iff we have *i* zeros at point in the column when we change value anche similar for ones(**to be exaplained better**)
- the c value and a bool to indicate how a column start

The column data II

example

If we have a column:

c = 00001110001111111000011111111

We save:

h = 000100100100000100010000000(1)

u = 00010010001 (to rappresent 4,3 and 4 zeros)

v = 0010000010000001 (to rappresent 3,6 and 7 ones)

The column data III

example

If we want to obtain, for example, the number of zeros before and index i, for example i=18:

- we rank h to obtain the run that contain i, rank_h(18) = 4
- we know that the column start with 0 so we are in a run of zeros and we have $\left|\frac{4}{2}\right| = 2$ run's of zeros before
- we know that the number of zeros in the previous complete runs is $select_u(2) + 1 = 7$
- remain zeros in the run to compute are given by $i (select_h(4) + 1)$

- The Old Idea
- The New Idea
- BitVector Version
- Matching Statistics

Matching Statistics and RLPBWT

Some definitions

- for every run in a column of the PBTW with define the **threshold** as the index of the minimum *lcp value* (and we save it as a sparse bitvector of the same length of a column with 1 in these positions)
- for every run in a column of the PBTW with define the prefix array samples as the prefix array value at the begin of the run and at the end
- we define matching statistics as a two components (row, len) vector MS of the same length of the query such that $\forall k \in [0, |z|)$:
 - $panel_{row}[k (len+)1..k] = z[k (len+1)..k]$
 - z[k (len + 1)..k + 1] doesn't match with any row in the panel
- we compute *row* and *len* in two different scans
- we need random access to the panel. At this time we are using a bitvector for every column of the panel but we can use a data structure, called SLP, with a very low memory cost but with high access times

Matching Statistics using LCE queries

- using an SLP we can make Longest Common Extensions (LCE) queries.
 Given two row of the panel and a column we can compute the longest common suffix as far as the given column.
- as for the case of the thresholds study we starts from the bottom-left symbol in the panel and we move left to right using LF-mapping
- lacksquare if we have a match we continue adding 1 every time to the *len* of MS
- every time we have a mismatch we look for the previous and the next good symbol in the column. Using the prefix array samples we have the original-row index of the end of the previous run and the original-row index of the begin of the next run (if they exists)
- if we are in a column with only the wrong symbol we restart the computation from the last row of the original panel
- we compute the two LCE and we take the longest
- next *row* in the *MS* will be the index of the row with the maximum *LCE* and the *len* of the *MS* will be the length of the *LCE* plus 1

Extract the matching rows I

The idea on the RLBWT

On the RLBWT we can list every starting position of a pattern in a text, of length n, using two functions. Given an SA value p:

- $\varphi(p) = SA[ISA[p] 1]$ or *NULL* if ISA[p] = 0
- $\varphi^{-1}(p) = SA[ISA[p] + 1]$ or *NULL* if ISA[p] = n 1

In other words the two functions gives pre previous and the next values of the *SA*.

Extract the matching rows II

The idea on the RLPBWT

We can use something similar on the RLPBWT to understand, when we have a match ending in column k, which rows are matching, having knowledge of one of this rows, thanks to the matching statistics row value. In order to obtain this result we need an additional data structure:

- lacksquare a sparse bit vector matrix for the φ . Given a row and a column we have a 1 in this position iff that row is a run head in that column
- **a** a sparse bit vector matrix for the φ^{-1} . Given a row and a column we have a 1 in this position iff that row is a run end in that column
- two matrix of int_vector, for the two panel, with a value for every 1 in the sparse bit vector matrices

In addition we use the last prefix array to complete the informations of the last column, for examples for equal rows in panel.

Infact the key idea is to record every time two consecutive rows in a certain order as far as column k-1 change their relative order in column k.

This data structure could be computed only at request and take less space than a complete prefix array for every column.

We use φ and φ^{-1} to make queries from a given row and a given column. To make this type of query we simply rank the given column in the bitvector at the given row and we give the result based on the support vector.

So every time we have a match we could start from row value and go up/down as far as the row obtained from the two queries is "good". Infact we can use LCE function or simply the random access to check the matches with the near rows in the permutation at column k.

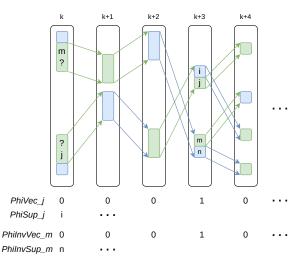

Figura: In this example we have $\varphi(j,k)=i$ and $\varphi^{-1}(m,k)=n$: Notice that k could also be k+1, k+2 or k+3.
